November 24, 2010

**Abstract:** We analyse the efficiency effects of the initial permit allocation given to firms with market power in both permit and output market. We examine two models: a long-run model with endogenous technology and capacity choice, and a short-run model with fixed technology and capacity. In the long run, quantity pre-commitment with Bertrand competition can yield Cournot outcomes also under emissions trading. In the short run, Bertrand output competition reproduces the effects derived under Cournot competition, but displays higher pass-through profits. In a second-best setting of overallocation, a tighter emissions target tends to improve permit-market efficiency in the short run.

**Keywords:** Emissions trading, Initial permit allocation, Bertrand competition, EU ETS, Endogenous technology choice, Kreps and Scheinkman

**JEL classification:** L13, Q28, D43

# 1 Introduction

Prices reflect scarcity in well-functioning markets. In its first trading phase 2005-2007, the European Union Emissions Trading Scheme (EU ETS) seemed to struggle with this principle. Following the information release that the market was long, the price of EU Allowances (EUA) after a first sharp fall began to rise again, and stayed in a range of €15–18 for a period of 6 months (Alberola *et al.* 2008).<sup>1</sup> During this period, it was disconnected from almost all market fundamentals. Studies, implicitly assuming that all of the 11,000 covered installations were actively trading, did not find evidence of market power (*e.g.*, Convery and Redmond 2007, Trotignon and Delbosc 2008).<sup>2</sup> But only a few companies and sectors (mainly electric utilities, banks, and some hedge funds) were active in the market in the early years. With regard to the initial allocation only the power sector was short in the first trading period (Ellerman and Buchner 2008). In addition, this sector can pass-through the costs to consumers generating so-called wind-fall profits.<sup>3</sup>

We seek to explain a positive allowance price, starting from the possibility of an overall excess permit allocation received for free in a situation where two or more firms have market power in both permit and product market and trade permits. We examine two kinds of models with permit/product market interaction. In our long-run models, the choices of production technology and production capacity are endogenous, technology choice determines the marginal cost of output production and the level of emissions per unit of production. In the short-run model, technology and capacity are exogenous and thus fixed.

Our modeling is inspired by Kreps and Scheinkman (1983). We modify their framework in two ways. For the long-run analysis, we introduce, following von der Fehr (1993), an additional initial stage of technology choice and a stage of permit choice. Hence, if

---

<sup>1</sup>The EUA spot price, from a high of almost €30 in late April 2006, plummeted 54% in only four days before unexpectedly rebounding and holding in the mentioned range from April-October 2006. Then it declined reaching some cents in 2007.

<sup>2</sup>They determine the market concentration (Herfindahl-Hirschman Index) for companies and single sectors, comparing the initial allowance allocation to the total number of permits initially allocated.

<sup>3</sup>Windfall profits accrue to a firm, when it receives inputs (such as permits) for free but incorporates their opportunity cost in its pricing decisions. Sijm *et al.* (2006) estimate for Germany and the Netherlands in 2005 a pass-through rate of 60-100% with windfall profits of about €6 Bn.

the permit market is interpreted as an input market, our analysis can be considered as a particular case of market-making oligopoly, in the sense of Loertscher (2008).<sup>4</sup> In the short-run analysis, we fix technology and capacity choices, and focus on the case of price competition in the product market. We thus complement the typical analysis in the literature on market power in emissions markets and related product markets by consideration of the case of Bertrand output oligopoly. Given that in many non-competitive product markets firms compete in prices rather than quantities (*e.g.*, Loertscher 2008), and that, in particular, for electricity markets Cournot competition is typically found to deliver too few competitive results, the almost exclusive focus on Cournot output competition in this literature seems rather surprising.<sup>5</sup>

The distinction between long run and short run is motivated from the different degrees of flexibility in technology and capacity choice between a mature and a newly established ETS. In a new ETS, the technology and capacity determined in the pre-ETS environment may not be optimal.<sup>6</sup> Moreover, while in the long run policy makers will have better information how the allocation of permits relates to each firm's emissions level, in the short run policy makers have only limited *ex-ante* knowledge of how firms will react to an ETS. As a consequence, we expect in the long run no firm with market power is allocated more permits than it needs to meet its regulatory obligations. In the short run the policy makers' choice of the initial permits allocation to a firm with market power is unrestrained (other than to be positive).

For the long run, we show that the key result by Kreps and Scheinkman (1983) – that quantity pre-commitment with Bertrand competition leads to Cournot results – still holds under existence of an emissions trading scheme (ETS) with permit/product

---

<sup>4</sup>While our long-run analysis was developed directly based on Kreps and Scheinkman (1983), we extend Loertscher's analysis, for the duopoly case, by allowing for an initial endowment of the input good and analysing initial allocation effects. Moreover, we demonstrate that, under a costly capacity constraint, also Cournot-Bertrand (input-output) competition yields Cournot outcomes while Loertscher sticks to the cases of Cournot-Cournot and Bertrand-Bertrand competition.

<sup>5</sup>See Montero (2009) for an overview over this literature. Two exceptions, considering Bertrand competition, constitute Requate (1993) and Montero (2002a). Requate states, in a setting with only a two-firm industry, that the number of permits issued may act as a capacity constraint, leading to a Kreps-and-Scheinkman style result. Montero compares R&D incentives from environmental-policy instruments under perfect and imperfect output and permit markets in Cournot and Bertrand output duopoly. He sticks to overall permit scarcity and does not treat initial allocation effects.

<sup>6</sup>For emissions-intensive industries, technology will tend to be too dirty and capacity too high.

market interaction. In equilibrium, firms will hold permits such as to exactly cover their emissions. Total industry emissions and the permit price are positively related to the size of the free initial permits allocation to a firm of that sector.

In the short run, we study how a marginal change in the initial permit allocation to a firm impacts on its equilibrium permit holdings, the permit price, and product market outcomes under Bertrand competition. We consider both elastic and inelastic product demand. In extension to the previous literature, we distinguish an interior and a boundary solution depending on whether, in equilibrium, at least one firm holds excess permits or all firms are constrained in their emissions. In the interior solution, we identify two kinds of distortionary effects: the Hahn (monopsony/monopoly) effects (after Hahn 1984), and the pass-through profit effect. Previously, they have implicitly been distinguished, *e.g.*, by DiSegni Eshel (2005) in a dominant-firm setting, but not considered for Bertrand competition. Pass-through profits, the pass-through profit effect, and thus the effect on the permit price are greater under Bertrand than under Cournot competition, and increase with demand inelasticity. On the boundary, a change in the initial allocation leaves permit holdings, permit price, and product price unaffected. Finally, we discuss the threat of technology switching as an additional explanation for the permit price phenomenon.

A positive allowance price in the face of an overall excess permit allocation, as it occurred in the first EU-ETS phase, can, hence, also be explained if a permit-and-product-market oligopolist (whose initial permit allocation differs from its final permit holdings) competes in the product market in prices. As associated with an interior solution, this price development is particularly likely to occur under an overall excess allocation of permits and when permits are initially given for free. Conversely, in the short run, a boundary solution and thus increased permit-market efficiency are the more likely the stricter the emissions target. We do not explicitly investigate an alternative permit allocation mechanism or the implementation of the social optimum. From our study nevertheless a case for auctioning of the initial permit allocation derives, as it will help reduce pass-through profits and thus the distortionary effects of an ETS in both the short

and the long run.

Section 2 introduces the model framework we use. Section 3 develops the short-run analysis. Section 4 treats the long-run analysis. We discuss our results in section 5. Section 6 concludes.

## 2 The Model

Consider a one-period model with four stages of an economy with polluting production and an emissions trading system in which initial permits are allocated for free. Competing firms with market power on both output and permit markets maximise profits

$$\Pi_i = p_i \cdot q_i - q_i \cdot c_i(\theta_i) - (x_i - x_i^0) \cdot \phi(X) - f_i(K_i, \theta_i) \quad \text{such that} \quad q_i \leq K_i, \quad (1)$$

where  $p_i$  is the price charged by firm  $i$ ,  $q_i$  is the production quantity of firm  $i$ ,  $c_i$  is the average production cost of firm  $i$  (assumed to be constant and equal to marginal cost),  $\theta_i \in [0, 1]$  is firm  $i$ 's technology parameter,  $x_i$  and  $x_i^0$  are the final and initial holdings of permits for firm  $i$ ,  $\phi(\cdot)$  is the market clearing permit price,  $X = x_i + x_j$  is the combined permit holding of firms  $i$  and  $j$ ,  $f_i$  is the capacity installation cost of firm  $i$  and  $K_i$  is firm  $i$ 's capital.<sup>7</sup> Emissions are by-produced according to the function

$$e_i(q_i, \theta_i) = q_i \cdot (1 - \theta_i). \quad (2)$$

In the permit market there is, moreover, a competitive fringe of polluting firms whose product is no substitute for the output of the firms of the first two types. The competitive fringe in the permit market ensures that the permit supply (price) function,  $\phi$ , is increasing with respect to the permit holdings of the market power firms.<sup>8</sup> Throughout we assume a fixed overall level of permits, which may exceed the total amount of

---

<sup>7</sup>We adopt the convention that the subscript  $j$  indicates  $\neq$ . The assumptions on the characteristics of the functions used are set out below.

<sup>8</sup>To motivate this interpretation of  $\phi$  consider the structure of the permit market: at any given permit price, the competitive fringe will demand some proportion of the fixed level of permits, with the level of demand decreasing with permit price (von der Fehr 1993).

emissions from the sectors covered by the ETS.

We consider three formulations of this model. In the long-run models the choices of production technology and production capacity are endogenous, technology choice determines both marginal output production cost and the level of emissions per unit of production. In the short run technology and capacity are exogenous.

**Model 1** *Long-run Bertrand model*

1. *Firms choose a production technology.*
2. *Firms install a costly production capacity.*
3. *Firms trade emissions permits.*
4. *Firms compete over prices in the product market.*

The profit function as given generally in (1) for firm  $i$  in the long-run Bertrand model (henceforth: the Bertrand model) depends on the price it sets, its output, its technology parameter, its permit holdings and its capital, so that  $\Pi_i^B(p_i, q_i, \theta_i, x_i, K_i)$ .

**Model 2** *Long-run Cournot model*

1. *Firms choose a production technology.*
2. *Firms compete over quantities in the product market.*
3. *Firms trade emissions permits.*

The profit function in (1) for a typical firm in the long-run Cournot model (henceforth: the Cournot model) depends on its quantity produced, its technology parameter, its permit holdings and its capital, so that  $\Pi_i^C(q_i, \theta_i, x_i, K_i)$ . Note that in the Cournot model  $p_i$  in (1) is to be replaced by the market clearing price  $P$  which depends on the sum of outputs produced by the two firms.

**Model 3** *Short-run model*

1. *Firms trade emissions permits.*

2. *Firms compete over prices in the product market.*

As technology and capacity are exogenous, in the short-run model the last term of the profit function (1) and the capital restriction vanish and marginal output production costs will only depend on the amount of output produced, so that  $\Pi_i(p_i, x_i)$ .

For the subsequent analysis we invoke the following assumptions.<sup>9</sup>

**Assumption 1** *The marginal cost function  $c(\theta): [0, 1] \rightarrow \mathbb{R}_0^+$  is constant in quantities and satisfies  $\frac{\partial c}{\partial \theta} < 0$  for all  $\theta \in [0, 1]$ .*

**Assumption 2** *The permit price function  $\phi(X): \mathbb{R}_0^+ \rightarrow \mathbb{R}_0^+$  is non-decreasing, twice continuously differentiable, convex, and satisfies  $\phi(0) \geq 0$ .*

The assumption of a non-decreasing permit price function merely reflects the existence of the competitive fringe. Firms in the competitive fringe behave as per Montgomery (1972). The permit price is a function of the permit holdings of the market power firms and is therefore endogenous to the model.

Following Kreps and Scheinkman (1983: 328), we further require:

**Assumption 3** *The output price function  $P(q)$  is strictly positive on some finite interval  $(0, Q)$ , on which it is twice-continuously differentiable, strictly decreasing, and concave. For  $q \geq Q$ ,  $P(q) = 0$ .*

**Assumption 4** *The installation cost function  $f(q, \theta): \mathbb{R}_0^+ \times [0, 1] \rightarrow \mathbb{R}_0^+$  is twice continuously differentiable, convex, and satisfies  $f(0, \theta) = 0$ ,  $\frac{\partial f}{\partial q} > 0$  and  $\frac{\partial f}{\partial \theta} > 0$  for all  $q \in \mathbb{R}_0^+$  and  $\theta \in [0, 1]$ .*

Throughout we focus on the situation where both firms produce a positive amount in equilibrium, and the equilibrium price is strictly positive. That is, we focus only on non-trivial solutions.

Finally, the structures of the games need some discussion. We start with the short-run model. Seeing the permit market as an input market and the product market as a

---

<sup>9</sup>The treatment of the technology parameter  $\theta$  is drawn from von der Fehr (1993).

spot market, the given structure may seem natural: having received the initial allocation of permits at the beginning of an ETS firms first seek to cover their permit demand before engaging in the product market. The structure fits equally well if the permit market is interpreted as a forward market. For the case of electricity markets, the reverse structure might be more realistic: much electricity is traded forward determining at the same time the permit amount needed to comply with the ETS. We stick to the former structure because it produces the more interesting results.<sup>10</sup> That is, having the permit choice occurring before product market competition allows for cost raising strategies to be profitable and allows for the investigation of interior solutions in the short run model.

We adopt the same structure in the long-run Bertrand model. For the Cournot model the production decision is made before the permit holding is determined, so as to ensure our main result Kreps and Scheinkman holds. The interpretation of the long run results may be applied to both the Cournot and Bertrand models. Note that the Kreps and Scheinkman result of the long-run analysis in section 4 is robust against a simultaneous inversion of stages 2 and 3 in both the Cournot and Bertrand models.

### 3 Short-Run Analysis

In the short run product demand is often relatively inelastic. Situations where demand may be considered perfectly inelastic in the short run include staple foods and electricity. Therefore, we analyze the cases of both elastic and inelastic product demand. In order to prevent monopolistic style behaviour to occur when the difference in the cost structures between oligopolistic firms is large, we consider two *types* of identical firms and there to be at least two firms of each type. In addition, we take the number of firms to be fixed and suppose there are enough firms to meet demand. This ensures that the capacity constraint does not directly influence the results in the short run. This seems reasonable

---

<sup>10</sup>Our structure is also considered in von der Fehr (1993: subsection 3.1) for Cournot output competition and, similarly, in Loertscher's basic model. DiSegni Eshel (2005), von der Fehr (1993: subsection 3.3) consider simultaneous (spot) market competition for product and permits. Allaz and Vila (1993) study the forward market interpretation for a Cournot spot market, Mahenc and Salanié (2004) for a Bertrand spot market (Liski and Montero (2006) analyse the repeated context), but without focus on initial allocation effects.

in the initial stages of an ETS where overall production levels are likely to fall relative to business-as-usual baselines.

Firms of type  $a$  have lower marginal production costs but a higher emission intensity than firms of type  $b$ ,  $d_i$  designates the emission intensity per unit of production:<sup>11</sup>

$$c_a + d_a \cdot \phi(X) < c_b + d_b \cdot \phi(X) \quad \text{with} \quad d_a > d_b. \quad (3)$$

In the short run, a firm faces a fixed emissions intensity. The only abatement opportunity available to a firm is thus to reduce production. We require compliance with the ETS<sup>12</sup> such that

$$x_i \geq d_i q_i \quad (i = a, b). \quad (4)$$

In the short run, we impose capacity constraints that ensure that firms of a single type cannot satisfy the entire market. In the long run model, these capacity constraints will become endogenous. For the inelastic case we replace Assumption 3 with assumption 6 (Assumption 2 continues to apply):

**Assumption 5** *The marginal cost function  $c(q): \mathbb{R}_0^+ \rightarrow \mathbb{R}_0^+$  is constant and finite for the closed interval  $[0, \bar{q}_i]$  and not defined for  $q > \bar{q}_i$ , so that firms have a capacity constraint at  $\bar{q}_i$ . The capacities,  $q_i$ , are such that  $\sum_{i \in A} \bar{q}_i < Q$ ,  $\sum_{i \in B} \bar{q}_i < Q$  and  $\sum_{i \in A, B} \bar{q}_i > Q$ .*

**Assumption 6** *Demand is perfectly inelastic and fixed at some quantity  $Q > 0$ .*

In contrast to Assumption 1, in the inelastic case marginal costs are constant and each firm has an exogenous capacity constraint.

We solve the short-run model for sub-game perfect Nash equilibria using backwards induction beginning with the second stage.

---

<sup>11</sup>For example, type  $a$  could be coal-fired power plants, type  $b$  as gas-fired power plants or renewable generators with high fixed costs. The specification rules out the case where one plant is both cheaper to run and less emissions intensive. This case is not very interesting: the result is, intuitively, that the low-cost, low-emission firms should satisfy as much of the demand as possible at any carbon price, therefore industry emissions are independent of permit prices and initial allocations.

<sup>12</sup>This assumption is standard in the literature as most ETS impose large penalties for non-compliance. For example, in the first EU-ETS phase the non-compliance penalty was €40 per missing permit (in phase two €100) plus a ‘make-good provision’ requiring an extra permit surrendered the next year.

**Lemma 1** *Given efficient rationing, the second-stage pricing game contains a Nash equilibrium where each firm charges a price equal to the marginal cost (including carbon costs) of the least cost effective unit:  $p^* = c_b + d_b \cdot \phi(X)$  for all firms.*

The proof is given in Appendix A.1. It will clearly be profitable for type-*a* firms to produce to their capacities, and to charge the highest price possible. Type-*b* firms compete over the residual demand under Bertrand competition with constant marginal costs. As is well known, the solution for this problem is for type-*b* firms to charge price equal to marginal cost. Type-*a* firms want to price as high as possible: given efficient rationing, they can charge equal to the marginal cost of type-*b* firms and still sell their full capacity. Thus the solution is for all firms to charge equal to the marginal cost of type-*b* firms.

In the first stage of the game, firms seek to maximise their profits (1) adapted for the short-run case over their permit holdings given the optimal choice of the output price in the second stage and the compliance condition (4). We have to distinguish the cases of (a) an interior solution, where at least one firm holds more permits than required,  $x_i^* > d_i q_i^*$ , and (b) a boundary solution, where all permits are utilised to cover actual emissions,  $x_i^* = d_i q_i^*$  for all firms (see Figure 1 for an illustration). In equilibrium, we

**Figure 1:** Distinction of (a) interior and (b) boundary solution in permit-choice game.

require the following first- and second-order conditions to hold for all firms that are not

constrained by their emissions constraint:<sup>13</sup>

$$\frac{\partial \Pi_i}{\partial x_i} = \frac{\partial p}{\partial x_i} q_i + \frac{\partial q_i}{\partial x_i} p - \frac{\partial q_i}{\partial x_i} c_i - \phi(X) - (x_i - x_i^0) \frac{\partial \phi}{\partial x_i} = 0 \quad (5a)$$

$$\frac{\partial^2 \Pi_i}{\partial x_i^2} < 0. \quad (5b)$$

**Remark 1** *Condition (5b) is necessary to ensure the solutions to conditions (5a) characterise a maximum. Sufficient, but not necessary, for condition (5b) to hold is that  $\phi(X)$  is linear.*

The proof is given in Appendix A.2. In a boundary solution, the optimal permit holding constrains production, so that  $x_i^* = d_i q_i^*$ .

Proposition 1 summarises the effects of an increase in the initial permit allocation to a firm on its optimal permit holdings, the permit price, and the product price.

**Proposition 1** *Given a reallocation of initial permits from the competitive fringe to a market-power firm does not induce a change of the marginal unit of production in the first-stage permit-choice problem, it will,*

a) *in an interior solution, increase*

- *the number of permits the firm holds in equilibrium,*
- *the permit price, and*
- *the product price (i.e., increase pass-through profits),*

b) *in a boundary solution, have no effect on*

- *the number of permits the firm holds in equilibrium,*
- *the permit price, or*
- *the product price (i.e., there is no additional pass-through profit).*

*These results hold irrespective of whether demand is perfectly inelastic or elastic.*

---

<sup>13</sup>For brevity,  $\frac{\partial p}{\partial x_i} \equiv \frac{\partial p}{\partial \phi} \frac{\partial \phi}{\partial x_i}$ , and  $\frac{\partial q_i}{\partial x_i} \equiv \frac{\partial q_i}{\partial p} \frac{\partial p}{\partial \phi} \frac{\partial \phi}{\partial x_i}$

**Proof.** a) Let  $x_i^*$  be the solution to problem (5a),  $\frac{\partial \Pi_i}{\partial x_i} = 0$ . The second derivatives  $\frac{\partial^2 \Pi_i}{\partial x_i \partial x_i^0} = \frac{\partial \phi}{\partial x_i} > 0$  and  $\frac{\partial^2 \Pi_i}{\partial x_i^2} < 0$  (see also the proof of Remark 1) together imply both  $\frac{\partial x_i^*}{\partial x_i^0} > 0$  and  $\frac{\partial \phi}{\partial x_i^0} > 0$  (Figure 2). Lemma 1 implies that the product price also increases.

b) By definition, a boundary solution indicates that compliance condition (4) holds with equality. The solution to the problem is, hence,  $x_i^* = d_i q_i$  ( $i = a, b$ ). As it is independent of  $x_i^0$ , the initial permit allocation has no bearing on the solution.  $\square$

We fix the marginal unit of production in Proposition 1 for clarity of results. As applied to power markets, for example, this assumption means that the merit order does not change. As demonstrated in section 3.1, permit prices may exhibit inertia near the switching price. Figure 2 illustrates the proof of Proposition 1.a. As  $x_i^0$  increases the

**Figure 2:** Illustration to the proof of Proposition 1.a.

optimal permit holding moves from  $x^*$  to  $x^{**}$ . As  $\frac{\partial^2 \Pi_i}{\partial x_i \partial x_i^0} > 0$ , an increase in  $x_i^0$  will increase the first derivative  $\frac{\partial \Pi_i}{\partial x_i}$  at all points along the profit curve. Thus, at the point where  $\frac{\partial \Pi_i}{\partial x_i} = 0$  for the original allocation of  $x_i^0$ ,  $\frac{\partial \Pi_i}{\partial x_i} > 0$  for the new allocation of  $x_i^0$ . As  $\frac{\partial^2 \Pi_i}{\partial x_i^2} < 0$ , there must be a value of  $x$  greater than the original  $x^*$  that will cause  $\frac{\partial \Pi_i}{\partial x_i} = 0$ . The increase in the initial permit allocation shifts the profit function up and to the right.

The likelihood of a boundary solution depends on the strength of the overall emissions target for the ETS.

**Corollary 1** *A tightening of the emissions target reduces the optimal holding of permits for each firm, and increases the range of production technologies that produce a boundary solution.*

The proof is given in Appendix A.3.

Permit-market efficiency requires all firms, in all industries, have the same marginal abatement costs in equilibrium. In our model all other industries are price takers in the permit market, and will, with Montgomery (1972), hold the efficient permit amount. To analyse permit-market efficiency we can thus focus on the firms with market power.

**Case 1** *Interior solution* ( $x_i^* > d_i q_i^*$  for at least one firm)

It may aid intuition to rewrite the first-order conditions (5a) in the form where marginal benefits equate marginal costs. Note that for the inelastic case  $\frac{\partial q_i}{\partial x_i} = 0$ :

$$\frac{\partial p}{\partial x_i} q_i - \frac{\partial q_i}{\partial x_i} c_i = \phi(X) + (x_i - x_i^0) \frac{\partial \phi}{\partial x_i} - \frac{\partial q_i}{\partial x_i} p \quad (6)$$

In the inelastic case, receiving an extra permit for free reduces a firm's marginal cost of purchasing another permit but leaves its marginal benefit unchanged. Thus, the firm seeks to purchase additional permits, which raises the permit price. In the elastic case, the marginal benefit from permit holding includes an additional term, capturing the cost reduction associated with the decreased production due to the increased permit holding; moreover, an additional cost term captures the revenue loss associated with the decreased production. As the price will exceed a firm's costs, marginal costs of an additional permit increase more than its marginal benefits. As purchasing an additional permit increases the product market price (reducing the quantity sold), the permit holding for each firm will be lower under elastic demand than under inelastic.

Equation (6) shows two distortionary effects which arise in relation to the oligopolists' market power in permit and product market. As qualitatively the same for elastic and inelastic demand, we only discuss the inelastic case. Note, first, that the marginal costs of an additional permit held in equilibrium are not equal to the permit price,  $\phi(X)$ . They also comprise a term for the extra amount to be paid for all other permits purchased,  $(x_i - x_i^0) \frac{\partial \phi}{\partial x_i}$ . It decreases in the initial allocation, increases with the permits held, and vanishes if the initial allocation exactly equals the firm's permit holdings in equilibrium. It is positive if and only if the firm is a net seller ( $x_i - x_i^0 > 0$ ), causing lower permit

holdings than under perfect competition (as discussed in detail in Hahn 1984). We call this effect the *Hahn monopsony* effect. For a net buyer ( $x_i - x_i^0 < 0$ ), it is negative, causing higher permit holdings than in the perfectly competitive case – the *Hahn monopoly* effect. Second, purchasing an extra permit implies a benefit due to the increase in revenue,  $\frac{\partial p}{\partial x_i} q_i$ . Compared to a situation without pass-through profits, profits and permit holdings are increased. We refer to this as the *pass-through profit* effect. Note that in the inelastic case, marginal changes in the initial permit allocation have no effect on production: in an internal solution the output is already at a maximum and is not affected by permit holdings.

Given the emissions target is set such that marginal social benefits of pollution reduction are equal to its marginal social costs, the permit market cannot be operating efficiently if a firm’s permit holdings exceed its emissions in equilibrium; non-utilised permits imply emissions below their socially efficient level.<sup>14</sup> The two kinds of initial allocation effects described have opposing impacts on market efficiency. When firms are net permit buyers, market efficiency is improved by the Hahn monopsony effect, but declines by the pass-through profit effect, as the initial allocation increases. When firms are net permit sellers, market efficiency declines due to both Hahn monopoly and pass-through profit effect, as the initial allocation increases. Thus, we would expect the efficient initial allocation here to be smaller than in the efficient case discussed by Hahn (1984).

If the permit market were perfectly competitive, then Hahn’s results for efficiency hold irrespective of the choice of Bertrand or Cournot competition. Using Bertrand competition here allows us to model pass-through profits in a more intuitive manner: changes in permit allocation directly affect prices in a Bertrand framework, rather than as a secondary flow on effect from quantity choices under Cournot competition. The Hahn effects will exist in a formulation with Cournot output competition, too, as will the pass-through profit effect. The size of the pass-through profit effect, however, is smaller with Cournot than with Bertrand. The purchase of an additional permit by any

---

<sup>14</sup>In a similar vein Smith and Yates (2003) show that non-emitting members of the economy purchasing and retiring permits (*e.g.*, environmental groups) is a signal of an inefficient market, although in their model the inefficiency stems from uncertainty over the optimal size of the emissions target.

firm will raise the permit price, raising the carbon-inclusive marginal costs of the least cost-effective firm. The extent of the pass-through profit effect is determined by the rate of transmission of this increase in marginal costs to the product market price. In our Bertrand formulation, where we have chosen to focus on the unique equilibrium where the price equals the marginal cost of the least cost-effective firm, this transmission rate is 100 per cent; under Cournot competition it will be less than 100 per cent. Pass-through profits cause, hence, greater distortions under Bertrand competition.

**Case 2** *Boundary solution* ( $x_i^* = d_i q_i^*$  for all firms)

In a boundary solution to the first-stage permit-choice problem, the results are independent of whether demand is inelastic or elastic. In both cases a small change in the initial permit allocation will not affect the solution to that problem; it will still lie on the boundary. The proof of Proposition 1 implies that with an increase in the initial allocation of permits the profit function shifts up and to the right.<sup>15</sup> Hence, a marginal increase in the initial allocation here simply raises the firm's profits. Thus, the pass-through profit effect still exists in the sense that the existence of a positive permit price implies that the product market price is higher than it would be if the price of permits was 0. But the initial permit allocation to a firm no longer affects the pass-through profit effect. As on the boundary the equilibrium permit holdings do not change, marginal changes in the initial permit allocation have no effect on production; permits are expensive enough that firms simply wish to minimise their holdings for a given quantity of production. All permits are utilised to cover actual emissions. For a boundary solution, the initial allocation of permits has no impact on efficiency because the solution is independent of the initial allocation of permits. In a more long-run view, however, the initial allocation of permits may affect the entry/exit decision of firms as a high initial allocation creates higher profits. Thus, at least one initial allocation of permits will lead to efficiency of the permit trading scheme. In practice, it would be extremely difficult to give the correct initial allocation to all firms, implying that least-cost emissions reductions are unlikely

---

<sup>15</sup>The stationary point of the profit function occurs at a higher level of permit holdings, and the initial wealth of the firm has increased (Figure 2).

to be achieved.

Hence, in the short run, when capacity and technology choice is fixed, the efficiency of an ETS depends much on whether firms with market power are constrained by the requirement to hold permits. (It is clear that when the potential for pass-through profits exists, the pattern of the initial allocation of permits may affect both the final distribution of permits amongst firms and the permit price, through the pass-through profit effect and Hahn effects.) If firms are constrained by the requirement to hold permits the initial allocation of permits affects firms' profits, but not their optimal permit holdings. In no circumstances does a marginal change in the initial allocation of permits affect the level of production in the short run when demand is perfectly inelastic. In the case of elastic demand (where the comparison is possible), the effect of permit allocations on permit prices is greater in Bertrand competition than Cournot competition.

### 3.1 Technology Switching

In this subsection we extend the analysis to consider the potential for technology switching. Because each firm has a fixed production technology, technology switching may only be observed at the industry level. We relax the assumption of equation (3), to allow type- $b$  firms to have lower marginal costs for some values of  $\phi(X)$ . As  $c_a < c_b$  and  $d_a > d_b$ , type- $a$  firms will be cheaper at low values of  $\phi$  (and type- $b$  firms cheaper at high values). We define the *technology-switching carbon price*,  $\bar{\phi}$ , as the value of  $\phi$  such that

$$c_a + d_a \cdot \phi(X) = c_b + d_b \cdot \phi(X) . \quad (7)$$

The impact of  $\bar{\phi}$  will depend on the elasticity of the function  $\phi(X)$ .

The inclusion of a switching price introduces a discontinuity in equation (5a). The assumption that firms price such that the least cost effective firm receives zero profits implies that the discontinuity is a downward (upward) shift in profit for type- $a$  ( $b$ ) firms as a marginal change in permit holdings induces a shift in  $\phi(X)$  from  $\bar{\phi} - \epsilon$  to  $\bar{\phi} + \epsilon$  for small  $\epsilon$ . Therefore, a type- $a$  firm would prefer the carbon price to be slightly below

(rather than slightly above) the switching price. At an industry level, overall production from type- $a$  firms would be larger when the carbon price is slightly below the switching price (as type- $a$  firms are relatively cheaper). This relatively higher production from type- $a$  firms may be viewed as industry-level technology switching.

As in order to produce a firm must hold a positive quantity of permits, the ability for type- $a$  firms to place downward pressure on  $\phi$  is constrained, whereas the ability for type- $b$  firms to place upward pressure on  $\phi$  is not. Thus when  $\phi(X)$  is relatively elastic, type- $b$  firms will purchase sufficient permits such that  $\phi(X) > \bar{\phi}$ . When  $\phi(X)$  is relatively inelastic, purchasing sufficient permits such that  $\phi(X) > \bar{\phi}$  may be prohibitively expensive for type- $b$  firms, and the carbon price may be below the switching point. Hence, the carbon price is more likely to be below (above) the switching price when type- $a$  ( $b$ ) firms have greater market power.<sup>16</sup> In particular, if type- $a$  firms have more market power than type- $b$  firms, and  $\phi(X)$  is relatively inelastic, then the switching price may act as an artificial ceiling for the carbon price.

## 4 Long-Run Analysis

We now turn to the long-run models, Models 1 and 2, of section 2. We solve the long-run models by first exogenously fixing technology choice and demonstrating the Kreps and Scheinkman result. To do this, we solve the Cournot sub-game for sub-game perfect Nash equilibria (SPNE) using backward induction. We show that the solution for the Cournot game is identical to the corresponding Bertrand formulation. We then endogenise technology choice and conduct comparative statics on the initial permit allocation. Again, we require full compliance with the emissions trading scheme, so that  $x_i^* \geq e_i^* \forall i$ .

### 4.1 Cournot Game

We solve the Cournot game, as presented in Model 2, beginning with the third stage, where each firm simultaneously maximises its profit (1) (with  $P(q_i + q_j)$  substituted for

---

<sup>16</sup>Factors that determine market power include, for example, the output market share, the initial allocation of permits and the comparative costs of production.

$p_i$ ) such that the full-compliance requirement holds ( $x_i^* \geq e_i^*$ ).

**Lemma 2** *For an initial permit allocation  $x_i^0 \leq e_i$ , the solution of the second-stage game is  $x_i^* = e_i^* = q_i^*(1 - \theta_i)$  for  $i = a, b$ .*

**Proof.** For all  $x_i \geq x_i^0$ ,  $\frac{\partial \Pi_i}{\partial x_i} = -(x_i - x_i^0) \frac{\partial \phi}{\partial x_i} - \phi(X) < 0$ . The solution follows.  $\square$

Thus, firms will only hold permits to cover their emissions exactly. The assumption that  $x_i^0 \leq e_i$  is sufficient but not necessary; the solution given in Lemma 2 above will still hold as long as the excess allocation of permits is not too large ( $\frac{\partial \Pi_i}{\partial x_i}$  still negative). The intuition is: the model requires that a firm cannot hold less permits than it produces emissions. This can, for example, be ensured by high non-compliance penalties. Also, it is not profitable for a firm to hold more permits than is necessary. Doing so involves an additional cost for no additional benefits as production and revenues have already been realised in the second stage of the game.<sup>17</sup>

By substituting  $x_i^* = e_i^* = q_i^*(1 - \theta_i)$  into equation (1), the first-stage quantity maximisation problem of firm  $i$ ,  $i = a, b$ , may be written as

$$\max_{q_i} \Pi_i^C = q_i \cdot P(q_i + q_j) - q_i \cdot c_i(\theta_i) - [q_i(1 - \theta_i) - x_i^0] \cdot \phi[\cdot] - f_i(q_i, \theta_i), \quad (8)$$

where  $\phi[\cdot] = \phi[q_i(1 - \theta_i) + q_j(1 - \theta_j)]$ .

**Lemma 3** *The SPNE for the two-stage game where firms compete under Cournot competition and then purchase emissions permits can be found by solving problem (8) simultaneously for all firms.*

**Proof.** Existence and uniqueness of the solution to problem (8) follow from Tirole (1988: 225n).  $\square$

---

<sup>17</sup>Note that this is different from our short-run model, where it may be profitable to hold excess permits to raise a rival's costs, or to manipulate the market.

## 4.2 Bertrand Game with Cournot Outcomes

Now turn to a Bertrand version of the game, with quantity precommitment, as given by Model 1. Again we solve for sub-game perfect Nash equilibria. We first analyse the stage-4 pricing game, for given technologies (stage 1), capacity constraints (stage 2) and permit holdings (stage 3). Kreps and Scheinkman (1983: 335) summarize the required results for the stage-4 pricing subgame in the following proposition which we reproduce adapted to our notation and setting for convenience. Let  $K_i$  denote the installed capacity of firm  $i$ ,  $q_i^*$  the solution to problem (8), and  $q_i(K_j)$  the optimal solution to problem (8) for a firm, when its competing firm installs capacity  $K_j$ , so that  $q_j \leq K_j$ .<sup>18</sup>

**Proposition 2** (*adapted from Kreps and Scheinkman (1983)*).

1. If  $K_i \leq q_i^*$  for the two firms,  $i = a, b$ , both firms name price  $p_a = p_b = p = P(K_a + K_b)$ , where  $K_a, K_b$  are the capacity constraints installed in stage 1. Thus each firm has revenue  $K_i \cdot P(K_a + K_b)$ .
2. If  $K_a \geq K_b$  and  $K_a > q_a^*$ , firm  $a$  has expected revenue  $q_a(K_b)P(q_a(K_b) + K_b)$  whilst firm  $b$  has a uniquely determined expected revenue between  $\frac{K_b}{K_a}q_a(K_b)P(q_a(K_b) + K_b)$  and  $q_a(K_b)P(q_a(K_b) + K_b)$ .
3. If  $K_b \geq K_a$  and  $K_b > q_b^*$ , firm  $b$  has expected revenue  $q_b(K_a)P(q_b(K_a) + K_a)$  whilst firm  $a$  has a uniquely determined expected revenue between  $\frac{K_a}{K_b}q_b(K_a)P(q_b(K_a) + K_a)$  and  $q_b(K_a)P(q_b(K_a) + K_a)$ .

We now determine the optimal permit holdings in the stage-3 game, noting that the permit choice does not directly affect the results of Proposition 2. The only impact permit holdings have on a firm's pricing decision is that they may act as an artificial capacity constraint, if  $x_i < K_i(1 - \theta_i)$ . When  $x_i \geq K_i(1 - \theta_i)$ , there is no impact on the pricing game as the cost of purchasing permits is, by assumption, sunk during the pricing game.

**Lemma 4** *Let  $K_i$  be firm  $i$ 's installed capacity,  $i = a, b$ . Then, its optimal permit holding is  $x_i^* = \bar{e}_i = K_i(1 - \theta_i)$ .*

---

<sup>18</sup>Note that the proof in Kreps and Scheinkman (1983) is for the case when marginal costs are 0. Here we have positive marginal costs. But this does not change the nature of the results for situations where both firms produce positive quantities (*ibid.*: 337).

The proof is given in Appendix A.4. The intuition is probably more instructive. A firm has no incentive to purchase more than  $\bar{e}_i$  permits. For, to do so would incur a cost that cannot be recovered, and has no strategic advantage – the rival firm will still be able to purchase the full amount of permits required, and regard this cost as sunk in the pricing game (stage 3). A firm also will never purchase less than  $\bar{e}_i$  in a consistent equilibrium. To do so would imply there was an over-investment in capacity. Clearly, then, a firm must purchase  $x_i^* = \bar{e}_i$  emissions permits.

As might be expected in a game with perfect information, the firms' choice of  $x_i$ , and the associated unit costs, can be calculated following the firm's capacity choice. Thus, the permit costs may be incorporated into installation costs at the stage-2 decision. As they are sunk during the stage-4 pricing game, permit costs are then indistinguishable from installation costs, which obviously are also considered as sunk. To state the next lemma we introduce the following function  $F$ , it may be considered a 'sunk cost function.'

$$F(K_i, \theta_i, K_j, \theta_j) \equiv f_i(K_i, \theta_i) + [K_i(1 - \theta_i) - x_i^0] \cdot \phi[K_i(1 - \theta_i) + K_j(1 - \theta_j)] . \quad (9)$$

**Lemma 5** *Assume  $0 \leq x_i^0 \leq K_i(1 - \theta_i)$ .<sup>19</sup> The cost function  $F(K_i, \theta_i, K_j, \theta_j): \mathbb{R}_0^+ \times [0, 1] \times \mathbb{R}_0^+ \times [0, 1] \rightarrow \mathbb{R}_0^+$  is twice continuously differentiable, and satisfies  $F(0, \theta_i, K_j, \theta_j) = 0$ ,  $\frac{\partial F(K_i, \theta_i, K_j, \theta_j)}{\partial K_i} \Big|_{K_i=0} > 0$  and  $\frac{\partial^2 F(K_i, \theta_i, K_j, \theta_j)}{\partial K_i^2} > 0$  for all  $K_i, K_j \in \mathbb{R}_0^+$  and  $\theta_i, \theta_j \in [0, 1]$ .*

The proof is given in Appendix A.5.

Stages 2 and 3 of Model 1 may be interpreted as a single-stage capacity installation process, where firm  $i$ 's profit,  $i = a, b$ , can be written as

$$\Pi_i^B = q_i \cdot P(q_i + q_j) - q_i \cdot c_i(\theta_i) - F_i(K_i, \theta_i, K_j, \theta_j) . \quad (10)$$

Thus, our game has the same form as the game presented in Kreps and Scheinkman (1983), with the exception that our installation cost function depends on the capacity of the rival firm. Lemma 4 demonstrates, however, that the choice of permit holdings is not affected by the rival firm's choice of capacity. Hence, our model presented in equation

---

<sup>19</sup>This assumption is not strictly necessary. The permit allocation must not be 'too' high, however.

(10) is equivalent to the model presented in Kreps and Scheinkman (1983).

Kreps and Scheinkman (1983) show that both firms will select quantities such that  $q_i^* = K_i$ , and, hence, such that the equilibrium price is determined by the first condition in Proposition 2.<sup>20</sup> We may therefore use the rewritten equation (10) to state:

$$\max_{q_i} \Pi_i^B = q_i \cdot P(q_i + q_j) - q_i \cdot c_i(\theta_i) - [q_i(1 - \theta_i) - x_i^0] \cdot \phi[\cdot] - f_i(q_i, \theta_i), \quad i = a, b, \quad (11)$$

where  $\phi[\cdot] = \phi[q_i(1 - \theta_i) + q_j(1 - \theta_j)]$ . Problem (11) is identical to problem (8), the equivalent problem for the Cournot case. We conclude:

**Proposition 3** *The two-stage game where firms compete under Cournot competition and then purchase emissions permits yields the same results as the three-stage game where each firm installs costly production capacity, purchases emissions permits and then competes under Bertrand competition. The equilibrium of both games can be found by solving problem (11) simultaneously for all firms.*

The Kreps-and-Scheinkman framework has received much attention over the past two decades. For our application of Kreps and Scheinkman the structure of the game is important. The key parameter is the timing of the permit-choice and quantity-competition stages (the capacity-installation stage in the Bertrand formulation). If capacity installation occurred after the purchase of permits, our function  $F$  would not exhibit the correct shape to allow the Kreps-and-Scheinkman result to hold. Note the symmetry between the Cournot and Bertrand formulations. In both formulations the quantity competition stage occurs before the purchase of permits. Changing the order of events in only one of the games invalidates the results. A similar Kreps-and-Scheinkman result could, however, be generated, if the first stage of both games was the purchase of permits.<sup>21</sup>

---

<sup>20</sup>Much of Kreps and Scheinkman (1983) is in fact dedicated to dismiss conditions two and three in Proposition 2 as off-equilibrium paths: when firms install excess capacity they intensify the price competition in the third stage of the game and reduce their profits.

<sup>21</sup>That varied situation may generate different results in the following subsection 4.3. We do not consider the case further as there is no clear economic intuition to support a firm purchasing emissions permits before it installs production capacity.

### 4.3 Effects of the Initial Permit Allocation on Permit-Market Efficiency

We now consider the technology choice stage of games 2 and 1. Both of these models are equivalent to the two-stage game where firms maximise the profit function as (identically) contained in problems (8) and (11) by first making a choice of technology,  $\theta_i$ , and then choosing a quantity of production. We use the two-stage formulation of the game for analytical ease and focus on the choice of technology.

The optimal strategy for a firm in the first stage is to choose  $\theta$  such that the following conditions of, respectively, first and second order hold:

$$\frac{d\Pi_i}{d\theta_i} = \frac{\partial\Pi_i}{\partial\theta_i} + \frac{\partial\Pi_i}{\partial q_i} \frac{dq_i}{d\theta_i} + \frac{\partial\Pi_i}{\partial\theta_j} \frac{d\theta_j}{d\theta_i} + \frac{\partial\Pi_i}{\partial q_j} \frac{dq_j}{d\theta_i} = 0 \quad (12a)$$

$$\frac{d^2\Pi_i}{d\theta_i^2} < 0 . \quad (12b)$$

**Remark 2** *Condition (12b) is required to ensure that the value of  $\theta_i$ , found by solving condition (12a) is a maximum.*

For the rest of this section, we assume that condition (12b) holds.

Again, we study how a marginal change in the initial permit allocation to a firm affects the equilibrium. Unfortunately, its effect on technology and production choices of each firm is ambiguous. For, an increase in the initial permit allocation may lead to the installation of either cleaner or dirtier technology, and may either increase or decrease a firm's total cost function, depending on the relative slopes of the product demand, permit price and cost functions.<sup>22</sup> Moreover, the long-run model, unlike the short-run model, does not explicitly include a variable for permit holdings – they are uniquely determined

---

<sup>22</sup>Consider, for example, the case where an increase in the initial allocation promotes the installation of cleaner technology, which increases the firms' total cost of production. (As cleaner technology has lower installation costs, but higher marginal costs, it may either increase or decrease total costs.) Becoming less competitive the firm reduces production, causing a loss in profits from production. The reduction in production and the cleaner technology make it require fewer emissions permits (it is less polluting), causing a rise in profits from permit sale. The competing firm will, however, increase production levels, because it faces weaker competition. The competitor may also install dirtier technology, increasing its permit holdings and emissions levels. The net effect of the increase in the initial permit allocation will be an increase in total industry emissions.

by technology installed and quantity produced. Therefore, Hahn or pass-through profit effects cannot be isolated.

Proposition 4 summarises these effects. The results hold for all initial allocations of permits, and in particular irrespective of the sign of  $(x^* - x_0)$ .<sup>23</sup>

**Proposition 4** *A reallocation of initial permits from the competitive fringe to a firm with market power in the permit and product market will:*

- *increase total industry emissions,*
- *increase the price of permits.*

The proof is given in Appendix A.6.

Overall emissions for the economy do not change, as they are fixed by the exogenous supply of permits. Proposition 4 represents a change in the distribution of emissions between emissions, implying that the initial allocation of permits has efficiency effects. Again, the result is quite pessimistic when considering the ability of an ETS to provide least-cost emissions reductions. For least-cost abatement, all firms must have an equal MAC in equilibrium. The fact that emissions depend on the initial allocation implies that efficiency in the permit market can only occur if and only if regulators choose the ‘correct’ initial allocation of permits. Specifically, as the emissions, and therefore the MAC, of both firms depend on the free allocation of permits to *both* firms, the ‘correct’ initial allocations ensuring MAC is equalised across both firms is likely to be impossible to determine in a realistic situation.

Note, moreover, that permit-market efficiency does not imply an optimal level of investment in technology; it only implies that the MAC is equal for all firms, for a given level of technology. Optimal technology investment would imply a given level of production is produced at least total cost, which comprise both monetary and environmental cost. Permit-market efficiency is a necessary condition for optimal investment: without it a firm will not internalise the environmental externalities associated with their technology choice. Without being more specific about the relative slopes of product demand, permit

---

<sup>23</sup>The results are, of course, subject to Assumptions 3 and 4 and the structure of the games.

price and cost functions we cannot further detail how the initial allocation of permits might be used to promote social efficiency.

In the long run, it cannot be profitable for a firm to hold more permits than required for compliance. This makes intuitive sense, as any commitment to holding excess permits would not be expected to be sustainable in the long term. As a consequence, permit-market efficiency is more likely in the long than the short run.

## 5 Discussion

We discuss the argumentative application of our analysis to EU ETS and power sector in subsection 5.1. Subsection 5.2 considers our contribution to the literature on permit-market efficiency, the literature with a (more) long-run view in environmental economics, and to general industrial organisation. Subsection 5.3 contains policy implications.

### 5.1 Argumentative Application to EU ETS and Power Sector

As set out in the introduction, our analysis has a particular argumentative application to the EU ETS and the price phenomenon which occurred in its first trading phase 2005-2007. Our short-run analysis shows that some firms may have a strategic advantage from holding more permits than they have emissions. For example, if electricity generators (who face inelastic demand in the short run) were allocated permits such that their optimal permit choice is an interior solution to problem (5), then their actions would have directly contributed to the high permit prices. The possibility of individual excess permit holdings in equilibrium in the situation of an overall permit over-allocation with positive permit price has been treated in the literature, but only for the case of perfect or Cournot competition and elastic demand in the product market (*e.g.*, Maeda 2003, DiSegni Eshel 2005). We show that the Hahn monopsony and monopoly effects and a pass-through profit effect also occur under Bertrand competition and elastic or inelastic product demand (Proposition 1). In particular, in the interior solution, the pass-through profit effect becomes the bigger the more inelastic product demand, reaching 100 per

cent for inelastic demand, it is always bigger than under Cournot. Such very high pass-through rates of (opportunity) costs to consumers – hence, windfall profits – are in line with empirical evidence for the power sector (Sijm *et al.* 2006). This makes a case for the realism of considering Bertrand output competition in this setting. The empirical verification, however, whether certain companies did exercise permit market power in the permit market in the first EU-ETS phase hinges on the availability of firm-level data, especially of permit holdings and permit-market transactions. This data is currently still confidential.

The analysis in section 3.1 provides a potential explanation of the price movements in the EU ETS from April - October 2006. Sijm *et al.* (2006) estimate the carbon switching price (from coal to gas generation) as being approximately €18.5. Given that the carbon price is likely to have been relatively inelastic with respect to an individual firms' permit holdings, and that coal generators were awarded a large quantity of grandfathered permits (engendering them with potential market power), the observed prices during this period are consistent with the switching price acting as a price ceiling.

The long-run analysis in section 4 looks at the case where sufficient time has elapsed for firms to update and reinstall their production technology, as it may be expected in an established ETS. The extended Kreps-and-Scheinkman model then predicts that an increase in the free permit allocation to a sector with market power in permit and product market (such as conceivably the electricity industry) increases the permit price. In the long run, firms do not have an incentive to hold excess permits anymore because they can adjust their technology. This long-run effect will hardly have played a role for the price decline later in the first EU-ETS phase. The allowances rather lost their value because, in addition to their relative abundance, they could not be banked for the second phase.

## **5.2 Bertrand versus Cournot and Long-Run Considerations in the Literature**

Studies on permit-market efficiency have been following two modelling strategies. Either they have focused on the permit market, assuming there is no feedback from the output

market structure; or, if they include the product market, competition on it has typically been modelled in quantities.<sup>24</sup> Clearly, from a technical viewpoint, it is much easier to work with Cournot rather than Bertrand competition. Bertrand, however, is more general in that it can also treat inelastic product demand. Moreover, for the short-run case, it may provide results that are, *e.g.*, with respect to pass-through profit rates, closer to empirical findings than under Cournot competition. Whilst it is intuitively more natural for many markets to use Bertrand competition under an ETS, the fact that, under certain conditions, equivalence between the Bertrand and Cournot versions of the game can be established also under an ETS (Proposition 3), implies that we may use a Cournot game to approximate these cases.<sup>25</sup>

The long-run aspect with endogenous technology and capacity choice (as developed in section 4) has in the literature on permit-market efficiency thus far only been considered by von der Fehr (1993: subsection 3.3), but not with Bertrand competition or a focus of initial allocation effects. It adds in particular to contributions which compare R&D incentives from different environmental-policy instruments under different degrees of perfection of output and permit markets and, hence, also go beyond the question of static short-run efficiency (*e.g.*, Montero 2002b,a, Bruneau 2004). They show that under market power, contrary to perfect competition, command-and-control instruments may generate stronger incentives to innovate than market-based instruments. Moreover, their results for Cournot and Bertrand output competition do not in general coincide. This underlines the importance of both market-power issues and the distinct analysis of different

---

<sup>24</sup>Studies of the first type include, *e.g.*, Hahn (1984), Westskog (1996), Maeda (2003), Malueg and Yates (2009), Lange (2008), Wirl (2009); of the second type Misiolek and Elder (1989), von der Fehr (1993), Requate (1993), Sartzetakis (1997, 2004), Montero (2002a,b), DiSegni Eshel (2005). (Exceptions with respect to Cournot output competition include Requate (1993) and Montero (2002a), cf. footnote 5.) As a firm's main concern is to ensure it has enough permits to cover its emissions, market power in the permit market has typically been modelled with competition in quantities (only Lange (2008), Malueg and Yates (2009) and Wirl (2009) have recently also considered supply function equilibria).

<sup>25</sup>It is interesting to note that also the literature on power market regulation has been concentrating on Cournot competition and supply function equilibria (*e.g.*, Borenstein *et al.* 2000, Joskow and Tirole 2000, Gilbert *et al.* 2004, Willems *et al.* 2009) – although Wolfram (1999), for example, shows that both models predict markedly excessive mark-ups for British electricity spot prices in the 1990s. Also Bushnell *et al.* (2008) can approximate actual spot prices in several US states in their static Cournot framework only by taking into account (the frequently used) long-term contracts between utilities and retailers. Whether this softening effect of forward commitments on competition also holds in a dynamic setting is, however, doubted in the theoretical literature (Liski and Montero 2006).

forms of imperfect competition also in the more long-run view.<sup>26</sup>

Our long-run analysis was developed directly based on Kreps and Scheinkman (1983), who focus only on a single output market. Loertscher (2008) has recently summarized and extended the literature dealing with their framework to cover the situation where firms compete, as market-making oligopolists, on both input and output markets. Interpreting the permit market as the input market, our model may be considered a variation of Loertscher's model. We extend his analysis, for the duopoly case, by allowing for an initial endowment of the input good and analysing initial allocation effects. While we interpret this endowment as an initial allocation of emissions permits, it could also be seen as an initial inventory of stock. A second extension concerns the combination of forms of competition in input and output market. While Loertscher treats the cases of Cournot-Cournot and Bertrand-Bertrand (input-output) competition, we demonstrate that, under a costly capacity constraint, also Cournot-Bertrand competition yields Cournot outcomes.

Our analysis, like Loertscher, uses efficient demand rationing and does not consider uncertainty. According to the efficient rationing rule, customers with the highest reservation prices are serviced by the firm with the lowest prices. This rule is applied, for example, in electricity spot markets where a centralised authority, having received the utilities' price bids, clears the market according to it in intervals of several minutes. But it cannot be expected to hold in real-world markets in general. The use of alternative rationing rules can lead to different results (including mixed strategy equilibria) in the Kreps-and-Scheinkman second-stage pricing game over some range of the parameter (capacity) space (Davidson and Deneckere 1986). Efficient and proportional rationing lead to the benchmark results between which equilibrium behaviour is likely to be more aggressive than under Cournot competition, but less competitive than in the Bertrand case (Loertscher 2008). Moreover, the Kreps-and-Scheinkman result has been shown to be robust even under proportional rationing if capacity cost is sufficiently high (Davidson and Deneckere 1986) and independently of the prevailing rationing rule if all costs are sunk at the first stage and demand is uniformly elastic (Madden 1998). Reynolds and

---

<sup>26</sup>Interesting is also the idea to compare the option values of permits purchase and abatement measures in view of their (ir-)reversibility (*e.g.*, Chao and Wilson 1993).

Wilson (2000) find that, under uncertain demand at capacity installation, in many cases a symmetric equilibrium does not exist, even for identical firms. Our framework does not focus on symmetric firms, so we do not expect symmetric solutions. The introduction of uncertainty may be an interesting extension to our analysis (*e.g.*, Baldursson and von der Fehr 2004).

### 5.3 Policy Implications

The ETS design implications in the face of firms with market power in permit and product market one may derive from our analysis are independent of the kind of output competition, but differ to some extent for short and long run. In both cases, replacing free allocation by auctioning of the initial permit allocation will reduce pass-through profits, and is likely to lead to efficiency increases. In the short run, in an interior solution, it is, however, not clear whether full permit auctioning decreases the impact of the Hahn effects. For, permits are normally auctioned in conjunction to a secondary permit market. A firm with market power may purchase some permits at auction and some in the secondary market, leading to less efficiency gains than possible if it got all of its permits from the auction. (We assume an efficient auction.) A particular contribution of this paper is to explicitly treat the boundary solutions in the short-run analysis, where permit holdings, permit price and product price in equilibrium are independent from the initial permit allocation given to the firms. We show that a boundary solution is the more likely the more stringent the emissions target (Corollary 1).<sup>27</sup> Again, also with a sufficiently stringent target permit-market efficiency is more easily achieved with auctioning of the initial permits than if they are given for free. Note that in the EU ETS auctioning will be the dominant allocation method for the electricity sector from 2013 and will become more relevant for other sectors as free allocation is gradually phased out by 2027 (with the exception of free allocations to sectors with a risk of leakage) (EU 2009).

In the long run, in our case without banking of permits, holding more permits than required for compliance cannot be profitable for a firm. For equalisation of the firms' MAC

---

<sup>27</sup>In line with this conclusion, in relation to the earlier US SO<sub>2</sub> markets (with wide free allocation but stringent targets) market power did not occur as an issue (Joskow *et al.* 1998, Stavins 1998).

under the ETS, and hence least-cost abatement, auctioning of initial permits remains advantageous over free allocation. Indeed, due to the unsustainability of holding excess permits in the long term, permit-market efficiency is more likely in the long than the short run. However, the stringency of the emissions target does not impact on the likelihood of permit-market efficiency in the long run.

## 6 Conclusion

We study how the initial allocation of permits given to companies at the beginning of an emissions trading phase impacts on their behaviour and market outcomes, when firms have market power in permit and product market. We develop a long-run model with endogenous technology and capacity choice, and a short-run model with fixed technology and capacity. The latter extends the standard models of market power in ETS (*e.g.*, Hahn 1984, von der Fehr 1993, Westskog 1996) by consideration of the output market with Bertrand competition. The long-run analysis introduces permit trading in capacity-choice models, such as that of Kreps and Scheinkman (1983). We show that, in the short run, initial allocation effects derived with Cournot competition carry over to Bertrand output competition, with two extensions. The Bertrand case is more general in that it can also treat inelastic product demand; and it generates higher pass-through profit rates (similar to those which could be observed for the electricity industry under the EU ETS). In the long run, under endogenous technology and capacity choice, Bertrand competition yields Cournot outcomes also under an ETS, if corresponding structures of the two versions of the game are chosen. Qualifications in the literature with respect to the demand rationing rule apply. A crucial assumption in this paper is that the initial permit allocation is given to the firms for free. We show that in the short run (also under free allocation), permit-market efficiency is likely to increase with the strength of the emissions target. Further efficiency increases could be achieved by auctioning the permits.

Our analysis is based on static games under certainty. Whether the results are robust

in a dynamic setting, as may be more realistic especially in an established ETS, and how they may change if uncertainty is taken into account constitute interesting extensions for future research.

## Appendix

### A.1 Proof of Lemma 1

The profits for each firm will be given by  $Pi_i(p_i) = q_i(p_i - c_i - d_i \cdot \phi(X))$ . Note that we ignore the installation costs for short run analysis. For notational simplicity permit allocations are suppressed. Suppose all firms charge  $p = c_b + d_b \cdot \phi(X)$ . We investigate the effects of a unilateral deviation in prices. Let  $p^+ = p + \epsilon$  and  $p^- = p - \epsilon$  for positive  $\epsilon$ .

Clearly, for type b firms,  $Pi_b(p) = Pi_b(P^+) = 0$  and  $Pi_b(p^-) < 0$ . Therefore, no type b firm will deviate. For type a firms the efficient rationing, along with assumption 5, implies that  $q_a(p_a) = \bar{q}_a$  for all  $p_a \leq p$ . Therefore,  $Pi_a(p) \geq Pi_a(P^-)$  and  $Pi_a(p) > 0$ . Furthermore,  $Pi_a(p^+) = 0$  for a unilateral deviation to  $p^+$  by any type a firm.

Therefore the price  $p = c_b + d_b \cdot \phi(X)$  is an equilibrium.

□

### A.2 Proof of Remark 1

$\frac{\partial^2 \Pi_i}{\partial x_i^2} = \frac{\partial^2 p}{\partial x_i^2} \cdot q_i - q_i \frac{\partial^2 c_i}{\partial x_i^2} - 2 \frac{\partial \phi}{\partial x_i} - (x_i - x_i^0) \frac{\partial^2 \phi}{\partial x_i^2} < 0$  if  $\frac{\partial^2 c_i}{\partial x_i^2}, \frac{\partial \phi}{\partial x_i}, (x_i - x_i^0) \frac{\partial^2 \phi}{\partial x_i^2} \geq 0$  and  $\frac{\partial^2 p}{\partial x_i^2} \leq 0$ .  
 $\frac{\partial^2 c_i}{\partial x_i^2}, \frac{\partial \phi}{\partial x_i}, \frac{\partial^2 \phi}{\partial x_i^2} \geq 0$  hold from Assumptions 5 and 2.

$\phi(X)$  linear implies that  $\frac{\partial^2 \phi}{\partial x_i^2} = 0$ . For firms of type  $a$ ,  $\phi(X)$  linear also implies that  $\frac{\partial^2 p}{\partial x_i^2} = 0$ , and we are done. For firms of type  $b$ , some more work is needed.

$$\begin{aligned} \frac{\partial^2 \Pi_b}{\partial x_b^2} &= \left( \frac{\partial^2 p}{\partial \phi^2} \frac{\partial \phi}{\partial x_b} + \frac{\partial p}{\partial \phi} \frac{\partial^2 \phi}{\partial x_b^2} + \frac{\partial^2 p}{\partial c_b^2} \frac{\partial c_b}{\partial x_b} + \frac{\partial p}{\partial c_b} \frac{\partial^2 c_b}{\partial x_b^2} \right) \cdot q_b - q_b \frac{\partial^2 c_b}{\partial x_b^2} - 2 \frac{\partial \phi}{\partial x_b} - (x_b - x_b^0) \frac{\partial^2 \phi}{\partial x_b^2} \\ &= \left( d_b \cdot \frac{\partial^2 \phi}{\partial x_b^2} + 1 \cdot \frac{\partial^2 c_i}{\partial x_b^2} \right) \cdot q_b - q_b \frac{\partial^2 c_b}{\partial x_b^2} - 2 \frac{\partial \phi}{\partial x_b} - (x_b - x_b^0) \frac{\partial^2 \phi}{\partial x_b^2} \end{aligned}$$

from Lemma 1. So,

$$\frac{\partial^2 \Pi_b}{\partial x_b^2} = d_b \cdot \frac{\partial^2 \phi}{\partial x_b^2} - 2 \frac{\partial \phi}{\partial x_b} - (x_i - x_i^0) \frac{\partial^2 \phi}{\partial x_b^2},$$

which is negative when  $\phi(X)$  is linear.  $\square$

### A.3 Proof of Corollary 1

A tightening of the emissions target can be introduced to the model as an exogenous increase in the permit price function,  $\phi$ . An increase in  $\phi$  decreases  $\frac{\partial \Pi_i}{\partial x_i}$  and, by the same logic as presented in the proof of Proposition 1.a, reduces the equilibrium value of  $x_i^*$  for any given production technology (as represented by the continuous variable  $\theta$  in the long-run models, but exogenous and hidden in the short run model). All production technologies that previously produced a boundary solution will still produce a boundary solution. Also, there will be at least 1 new production technology that will produce a boundary solution (e.g. the production technology that previously gave the solution  $x_i^* = d_i q_i^* + \epsilon$  for small  $\epsilon$ ).  $\square$

### A.4 Proof of Lemma 4

Let  $\Pi(x_i, K_i)$  denote the profit of firm  $i$  as in equation (1) when it installs capacity  $K_i$ , purchases permits  $x_i$  and prices are determined as in Proposition 2, for a given choice of permits by the opposing firm. We begin by using forwards induction to eliminate  $x_i < x_i^*$ . We denote the capacity constraint implied by the permit holding  $x_i < x_i^*$  by  $\hat{K}_i = x_i / (1 - \theta_i)$ . Now,  $\Pi(x_i, \hat{K}_i) > \Pi(x_i, K_i)$ . This implies that the firm has ‘over-installed’ capacity in the first stage of the game, and we reject this situation as an equilibrium using the concept of forward equilibrium. For  $x_i > x_i^*$  the capacity constraint is  $K_i$ . Now,  $\Pi(x_i^*, K_i) > \Pi(x_i, K_i)$ . Hence, a firm will not install permits such that  $x_i > x_i^*$ . Therefore, firms will install permits such that  $x_i = x_i^*$  for  $i = a, b$ .  $\square$

## A.5 Proof of Lemma 5

The double continuous differentiability follows from Assumption 4. At  $K_i = 0$   $x_i^0 = 0$  by assumption, so  $F(0, \theta_i, K_j, \theta_j) = 0$ . For all  $K_i$  holds:  $\frac{\partial F}{\partial K_i} = \frac{\partial f_i}{\partial K_i} + (1 - \theta_i)\phi[K_i(1 - \theta_i) + K_j(1 - \theta_j)] + [K_i(1 - \theta_i) - x_i^0] \frac{\partial \phi}{\partial K_i} > 0$ . For all  $K_i$  holds:  $\frac{\partial^2 F}{\partial K_i^2} = \frac{\partial^2 f_i}{\partial K_i^2} + 2(1 - \theta_i) \frac{\partial \phi}{\partial K_i} + [K_i(1 - \theta_i) - x_i^0] \frac{\partial^2 \phi}{\partial K_i^2} > 0$ .  $\square$

## A.6 Proof of Proposition 4

Be  $E \equiv q_i(1 - \theta_i) + q_j(1 - \theta_j)$  the total emissions of the industry and note that  $\frac{d^2 \Pi_i}{d\theta_i dx_i^0} = \frac{\partial \phi}{\partial \theta_i} + \frac{\partial \phi}{\partial q_i} \frac{dq_i}{d\theta_i} + \frac{\partial \phi}{\partial \theta_j} \frac{d\theta_j}{d\theta_i} + \frac{\partial \phi}{\partial q_j} \frac{dq_j}{d\theta_i} = \frac{d\phi}{d\theta_i}$ . For  $\frac{d\phi}{d\theta_i} > 0$ ,  $\frac{d^2 \Pi_i}{d\theta_i dx_i^0} > 0$ , and, by condition (12b),  $\frac{d\theta_i}{dx_i^0} > 0$ , such that  $\frac{d\phi}{dx_i^0} > 0$ . For  $\frac{d\phi}{d\theta_i} < 0$ ,  $\frac{d^2 \Pi_i}{d\theta_i dx_i^0} < 0$ , and, by condition (12b),  $\frac{d\theta_i}{dx_i^0} < 0$ , such that  $\frac{d\phi}{dx_i^0} > 0$ . Then, with Assumption 2 and Lemma 2,  $\frac{dE}{dx_i^0} > 0$ .  $\square$
